PoKED: A Semi-Supervised System for Word Sense Disambiguation

Feng Wei

Abstract

In this paper, we propose a semi-supervised neural system, named Position-wise Orthogonal Knowledge-Enhanced Disambiguator (PoKED), which effectively supports attention-driven, long-range dependency modeling for word sense disambiguation tasks. The proposed PoKED system incorporates position-wise encoding into an orthogonal framework and applies a knowledge-based attentive neural model to solve the WSD problem. Our proposed unsupervised language model is trained over unlabeled corpora; then the pre-trained language model is used to abstract the surrounding context of polysemous instances in labeled corpora into context embeddings. We further use the semantic relations in the WordNet, by extracting semantic level inter-word connections from each document-sentence pair in the WSD dataset. Our experimental results from standard benchmarks show that our proposed system, PoKED, can achieve competitive performance compared with state-of-the-art knowledge-based WSD systems.

1. Introduction

Word Sense Disambiguation (WSD) is the task of mapping an ambiguous word in a given context to its correct meaning. For example, the word “bank” can either mean a “financial establishment” or “the land alongside or sloping down to a river or lake”, based on different contexts. WSD is an important problem in natural language processing (NLP), both in its own right and as a stepping stone to more advanced tasks such as machine translation, information extraction and retrieval, and question answering. WSD, being AI-complete, is still an open problem after over two decades of research. FollowingNavigli (Navigli, 2009), we can roughly distinguish between supervised and unsupervised approaches. Supervised methods require sense-annotated training data and are suitable for lexical sample WSD tasks where systems are required to disambiguate a restricted set of target words. However, the performance of supervised systems is limited in the WSD tasks as labeled data for the full lexicon is sparse and difficult to obtain. As the WSD task is challenging and has practical applications, there has been interest in developing unsupervised systems. These systems only require an external knowledge source (e.g., WordNet) but no labeled training data.

Example 1: An example about the importance of human semantic knowledge to the word sense disambiguation. Our experiment shows without incorporating human semantic knowledge, the model would wrongly predict a sense of the target word “document”. We believe the reason is due to the difficulty for the model to find a direct relationship through the given word and plain document. In the example, we can find the answer because we know “document” is a hypernym of “information”, or “information” is a hyponym of “document”. The example is selected from SentEval-15.

Document: This document is a summary of the European Public Assessment Report (EPAR). It explains how the Committee for Medicinal Products for Human Use (CHMP) assessed the studies performed, to reach their recommendations on how to use the medicine. If you need more information about your medical condition or your treatment, read the Package Leaflet (also part of the EPAR) or contact your doctor or pharmacist. If you want more information, on the basis of the CHMP recommendation, read the Scientific Discussion (also part of the EPAR).

Sentence: This [document] is a summary of the European Public Assessment Report (EPAR).

Answer: <noun.communication>[10] S: (n) document.01 (document[1:10:00::]), written document.01 (written_document[1:10:00::]), papers.01 (papers[1:10:00::]) (writing that provides information (especially information of an official nature))
shown in Example 1, such human semantic knowledge is essential to word sense disambiguation. In addition, we propose an end-to-end knowledge-based attentive neural WSD model, which explicitly uses the above extracted general knowledge to assist its attention mechanisms (Bahdanau et al., 2015). Our semi-supervised WSD system (PoKED), comprised of one unsupervised position-wise orthogonal nets (PoNet) and one supervised knowledge-enhanced word sense disambiguator (KED) based on attentive networks. We evaluate our system, PoKED, on standard benchmarks proposed by (Raganato et al., 2017) and show that the proposed model, utilizing the whole document as the context for a word to be disambiguated, achieves better performance than the previous state-of-the-art knowledge-based models.

2. Related Work

WSD approaches can be divided into two main categories: supervised, which require human intervention in the creation of sense-annotated datasets, and the so-called knowledge-based approach (Navigli, 2009), which requires the construction of a task-independent lexical-semantic knowledge resource, but which, once that work is available, uses models that are completely autonomous.

Supervised. A popular system, It makes sense (Zhong & Ng, 2010), takes advantage of standard WSD features such as POS-tags, word co-occurrences, and collocations and creates individual support vector machine classifiers for each ambiguous word. Newer supervised models use deep neural networks and especially long short-term memory (LSTM) networks, a type of recurrent neural network particularly suitable for handling arbitrary-length sequences. (Yuan et al., 2016) proposed a deep neural model trained with large amounts of data obtained in a semi-supervised fashion. This model was re-implemented by (Le et al., 2018), reaching comparable results with a smaller training corpus. (Raganato et al., 2017) introduced two approaches for neural WSD using models developed for machine translation and substituting translated words with sense-annotated ones. (Luo et al., 2018) proposed to combine labeled data and knowledge-based information in a recent work. (Uslu et al., 2018) proposed fastSense, a model inspired by fastText (Joulin et al., 2017) which – rather than predicting context words – predicts word senses. More recently, (Huang et al., 2019) construct context-gloss pairs and propose three BERT-based models for WSD. (Hadiwinoto et al., 2019) explore different strategies of integrating pre-trained contextualized word representations.

Knowledge-based. Knowledge-based models, instead, use the structural properties of a lexical-semantic knowledge base, and typically use the relational information between concepts in the semantic graph together with the lexical information contained therein (Navigli & Lapata, 2009). A popular algorithm used to select the sense of each word in this graph is PageRank (Page et al., 1999) that performs random walks over the network to identify the important nodes (Mihalcea et al., 2004). Another knowledge-based approach is Babelfy (Moro et al., 2014), which defines a semantic signature for a given context and compares it with all the candidate senses in order to perform the disambiguation task. (Chaplot & Salakhutdinov, 2018) proposed a method that uses the whole document as the context for the words to be disambiguated. It models word senses using a variant of the Latent Dirichlet Allocation framework (Blei et al., 2003), in which the topic distributions of the words are replaced with sense distributions modeled by a logistic normal distribution according to the frequencies obtained from WordNet. More recently, (Maru et al., 2019) introduced SyntagNet, a novel resource consisting of manually disambiguated lexical-semantic combinations. (Tripodi & Navigli, 2019) presented WSDG, a flexible game-theoretic model for WSD.

3. Position-wise Orthogonal

Knowledge-Enhanced Disambiguator (PoKED)

In this section, we describe in detail the proposed semi-supervised neural system (PoKED) for the WSD task. We aim to explore how position-wise embedding (unsupervised) could help the downstream WSD task, and how information from descriptive linguistic knowledge graphs (WordNet) can be incorporated into neural network architectures to solve and improve the linguistic WSD task.

3.1. Unsupervised Language Model (PoNet)

First, we elaborate on the proposed unsupervised language model named PoNet.

The linguistic distribution hypothesis states that words that occur in close contexts should have a similar meaning. It implies that the particular sense of a polyseme is highly related to its surrounding context. Moreover, humans decide the sense of a polyseme by firstly understanding its occurring context (Harris, 1954). Following this theory, our proposed model has two stages: training a position-wise orthogonal network (PoNet) that abstracts context as embeddings as shown in Figure 1, and performing knowledge-based attentional WSD classification over pre-trained context embeddings as shown in Figure 4.

3.1.1. Position-wise Encoding

(Zhang et al., 2015) recently proposed a method that is an alternative to commonly used sequence embedding representations, and achieved competitive results in language modeling. The authors proved a nice theoretical property
Back in the day, we had an entire bank of computers devoted to this problem.

that guarantees that extracted codes can almost uniquely encode any variable-length sequence of words into a fixed-size representation without losing any information.

Given a vocabulary $V$, where each word can be represented by a 1-of-$|V|$ one-hot vector. Let $S = \{w_1, \ldots, w_N\}$ denote a sequence of $N$ words from $V$, and $e_n$ denote the one-hot vector of the $n$-th word in $S$, where $1 \leq n \leq N$. Assuming $z_0 = 0$, the extracted code $z_n$ of the sequence from word $w_1$ to $w_n$ is as follows:

$$z_n = \alpha \cdot z_{n-1} + e_n \tag{1}$$

where $\alpha$ is a constant forgetting factor. Thus, $z_n$ can be viewed as a fixed-size representation of the subsequence $\{w_1, \ldots, w_n\}$. We can see that, according to the theoretical properties presented in (Zhang et al., 2015), any sequence of variable length can be uniquely and losslessly encoded into a fixed-size representation.

The main idea of position-wise encoding is to generate augmented encoding codes by concatenating two codes using two different forgetting factors. Each of these codes is still computed in the same way as the mathematical formulation shown in Equation (1). By using two different forgetting factors in the two codes, we can represent both short-term and long-term dependencies. Hence, our position-wise encoding can maintain the sensitivity to both nearby and faraway context.

3.1.2. Orthogonal Framework

More recently, a novel orthogonal framework (Zhang et al., 2016) has been proposed to learn neural networks in either supervised or unsupervised way. This framework introduces a linear orthogonal projection to reduce the dimensionality of the raw high-dimension data and then uses a finite mixture distribution to model the extracted features. By splitting the feature extraction and data modeling into two separate stages, it can derive a good feature extraction model that can generate better low-dimension features for the further learning process. More importantly, based on the analysis in (Zhang et al., 2016), the orthogonal framework has a tight relationship with neural networks since each hidden layer can also be viewed as an orthogonal model being composed of the feature extraction stage and data modeling stage. Therefore, the maximum likelihood based unsupervised learning as well as the minimum cross-entropy error based supervised learning algorithms can be used to learn neural networks under the orthogonal framework for deep learning. In this case, the standard back-propagation method can be used to optimize the objective function to learn the models except that the orthogonal constraints are imposed for all projection layers during the training procedure.

Simply put, in practice in terms of the orthogonal formulation, (Zhang et al., 2016) proposed to model $z$, which is heavily de-correlated but may still exist in a rather high dimension feature space, with a finite mixture model:

$$p(z) = \sum_{k=1}^{K} \pi_k \cdot f_k(z|\theta_k) \tag{2}$$

where $K$ is the number of mixture components, $\pi_k$ is the mixture weight of the $k$-th component ($\sum_{k=1}^{K} \pi_k = 1$), $f_k()$ denotes a selected distribution from the exponential family, and $\theta_k$ denotes all model parameters of $f_k()$.

An example of an orthogonal layer in deep feedforward networks is shown in Figure 2. For one hidden layer with input vector $x$ ($x \in \mathbb{R}^D$) and output vector $y$ ($y \in \mathbb{R}^G$), it is first split into two layers:

- The first layer is a linear orthogonal projection layer, which is used to project $x$ to a feature vector $z$ ($z \in \mathbb{R}^M, M < D$) and remove the noise signals by using an orthogonal projection matrix $U : z = Ux$.
- The second layer is a non-linear model layer, which converts $z$ to the output vector $y$ following the selected model $f_k()$ and a nonlinear log-likelihood pruning operation.

As the pseudo-language model (PoNet) is trained to predict the target word, the output layer is irrelevant to the WSD task. However, the remaining layers have learned the ability
Figure 2. The orthogonal framework is viewed as a hidden layer in deep feedforward networks.

PoKED: A Semi-Supervised System for Word Sense Disambiguation

3.2. Supervised Knowledge-based Attentive Model (KED)

In this section, we describe in detail the proposed supervised knowledge-enhanced attentive networks named KED for the WSD task, along with the data enrichment method with WordNet.

3.2.1. DATA ENRICHMENT WITH WORDNET

WordNet is a comprehensive lexical database for the English language (Miller, 1995), and is commonly used as the sense repository in WSD systems.

To provide our WSD model with explicit knowledge, we enrich the gloss information by extracting semantic level inter-word connections from each document-sentence pair in it; therefore we propose a WordNet-based data enrichment method.

Words in WordNet are organized into synsets, as shown in Figure 3, which in turn are related to each other through semantic relations, such as “hyponym” and “hypernym”. In our data enrichment method, we use the semantic relations of WordNet to extract semantic level inter-word connections from each document-sentence pair in the WSD dataset. For each word \( w \) in a document-sentence pair, we need to obtain a set \( Z_w \), which contains the positions of the document words that \( w \) is semantically connected to. Besides, when \( w \) itself is a document word, we also need to ensure that its position is excluded from \( Z_w \).

Given a word \( w \), its directly-involved synsets \( \Phi_w \) represents the synsets that \( w \) belongs to, and its indirectly-involved synsets \( \Phi_w \) represents the synsets that are related to those in \( \Phi_w \) through semantic relations. Based on the two concepts, we propose the following hypothesis: given a subject word \( w_s \) and an object word \( w_o \), \( w_s \) is semantically connected to \( w_o \) if and only if \( \Phi_{w_s} \cup \Phi_{w_o} \cap \Phi_{w_o} \neq \emptyset \). According to the hypothesis, Algorithm 1 describes the process of extracting semantic level inter-word connections from each document-sentence pair.

Given a word \( w \), we can easily obtain its directly-involved synsets \( \Phi_w \) from WordNet, but obtaining its indirectly-involved synsets \( \Phi_w \) is much more complicated, because in WordNet, the way synsets are related to each other is flexible and extensible. In some cases, a synset is related to another synset through a single semantic relation. For example, the synset “cold.a.01” is related to the synset “temperature.n.01” through the semantic relation “attribute”. However, in many other cases, a synset is related to another synset through a semantic relation chain. For example, first the synset “keratin.n.01” is related to the synset “feather.n.01” through the semantic relation “substance holonym”; then the synset “feather.n.01” is related to the synset “bird.n.01” through the semantic relation “part holonym”; and finally the synset “bird.n.01” is related to the synset “parrot.n.01” through the semantic relation “hyponym”; thus we can say that the synset “keratin.n.01” is related to the synset “parrot.n.01” through the semantic relation chain “substance holonym \( \rightarrow \) part holonym \( \rightarrow \) hyponym”. We name each semantic relation in a semantic relation chain as a hop. Therefore, the above semantic relation chain is a 3-hop chain. Besides, each single semantic relation is a 1-hop semantic relation chain.

Let us use \( \Gamma := \{ \gamma_1, \gamma_2, \ldots \} \) to represent the semantic relations of WordNet, and use \( \Omega_\phi \) to represent the synsets that a synset \( \phi \) is related to through a single semantic relation \( \gamma_i \in \Gamma \). Since \( \Omega_\phi \) is easy to obtain from WordNet, we can
Algorithm 1: Extract semantic level inter-word connections from each document-sentence pair

1: procedure EXTRACT(D, S)
   Input: Given a document D and a relevant sentence S.
   Output: Return the extraction results on D and S
2: for each document word \(d_i\) in D do
3:     \(Z_d \leftarrow \{j \in \{1, \ldots, n\} \mid \{\Phi_{d_i}, \bar{\Phi}_{d_i}, \Phi_{d_j} \neq \emptyset\}\} \) \(\triangleright\) Obtain the extraction results \(Z_d\)
4: for each sentence word \(s_i\) in S do
5:     \(Z_s \leftarrow \{j \in \{1, \ldots, n\} \mid \{\Phi_{s_i}, \bar{\Phi}_{s_i} \} \cap \Phi_{d_j} \neq \emptyset\}\) \(\triangleright\) Obtain the extraction results \(Z_s\)

Further obtain the synsets that \(\phi\) is related to through 1-hop semantic relation chains: \(\Psi_1 = \bigcup_{\gamma_i \in \Gamma} \Omega_{\phi_{\gamma_i}}\), the synsets that \(\phi\) is related to through 2-hop semantic relation chains: \(\Psi_2 = \bigcup_{\phi \in \phi_1} \bigcup_{\gamma_i \in \Gamma} \Omega_{\phi_{\gamma_i}}\), and by induction, the synsets that \(\phi\) is related to through \(k\)-hop semantic relation chains: \(\Psi_k = \bigcup_{\phi \in \phi_{k-1}} \bigcup_{\gamma_i \in \Gamma} \Omega_{\phi_{\gamma_i}}\). In theory, if we do not limit the hop counts of semantic relation chains, \(\phi\) can be related to all other synsets in WordNet, which is meaningless in many cases. Therefore, we use a hyper-parameter \(\tau \in \mathbb{N}\) to represent the maximum hop count of semantic relation chains, and only consider the semantic relation chains that have no more than \(\tau\) hops. Based on the above descriptions, given a word \(w\) and its directly-involved synsets \(\Phi_w\), we can obtain its indirectly-involved synsets: \(\bar{\Phi}_w = \bigcup_{\phi \in \Phi_w} \bigcup_{k=1}^{\tau} \Psi_k\).

3.2.2. KNOWLEDGE-BASED ATTENTIVE NEURAL MODEL

In this section, we describe in detail the proposed knowledge-based attentive model for word sense disambiguation. The key components of our model are the attention mechanisms, (i.e., knowledge-enhanced joint-attention and knowledge-enhanced self-attention). Knowledge-enhanced joint-attention aims to fuse the sentence representations into the document representations so as to obtain the sentence-aware document representations. Furthermore, knowledge-enhanced self-attention aims to fuse the sentence-aware document representations into themselves so as to obtain the final document representations. More importantly, the most remarkable feature of our model is that it explicitly uses the general knowledge extracted by the data enrichment method to assist its attention mechanisms.

Given a document \(D = \{d_1, \ldots, d_m\}\) and a relevant sentence \(S = \{s_1, \ldots, s_m\}\), the task is to predict a sense among a list of \(K\) candidates \(\mathcal{C} = \{c_1, \ldots, c_k\}\). As depicted in Figure 4, our proposed end-to-end supervised WSD model consists of five layers:

- Given a document-sentence pair, the **lexicon embedding layer** encodes the lexical features of each word to generate the document lexicon embeddings and the sentence lexicon embeddings. For each word, we use our pre-trained context embeddings based on position-wise encoding approach and orthogonal framework described in 3.1, and obtain its character embedding with a Convolutional Neural Network (CNN) (Kim, 2014).

For both the document and the sentence, we pass the concatenation of the word embeddings and the character embeddings through a shared dense layer with ReLU activation, whose output dimensionality is \(d\). Therefore we obtain the document lexicon embeddings \(L_D \in \mathbb{R}^{d \times n}\) and the sentence lexicon embeddings \(L_S \in \mathbb{R}^{d \times m}\).

- Based on the two lexicon embeddings, the **context embedding layer** encodes the contextual clues about each word to generate the document context embeddings and the sentence context embeddings. For both the document and the sentence, we process the lexicon embeddings (i.e., \(L_D\) for the document and \(L_S\) for the sentence) with a shared bidirectional LSTM (BiLSTM) (Hochreiter & Schmidhuber, 1997), whose hidden state dimensionality is \(\frac{1}{2}d\). By concatenating the forward LSTM outputs and the backward LSTM outputs, we obtain the document context embeddings \(C_D \in \mathbb{R}^{d \times n}\) and the sentence context embeddings \(C_S \in \mathbb{R}^{d \times m}\).

- Based on the two context embeddings, the **coarse-grained memory layer** performs both document-to-sentence and sentence-to-document attention to generate the preliminary memories over the document-sentence pair. First we use knowledge-enhanced joint-attention (discussed in section 3.2.3) to fuse \(C_D\) into \(C_S\), the outputs of which are represented as \(\tilde{G} \in \mathbb{R}^{d \times n}\). Then we process \(\tilde{G}\) with a BiLSTM, whose hidden state dimensionality is \(\frac{1}{2}d\). By concatenating the forward LSTM outputs and the backward LSTM outputs, we obtain the coarse-grained memories \(G \in \mathbb{R}^{d \times n}\), which are the sentence-aware document representations.

- Based on the coarse-grained memories, the **fine-grained memory layer** generates the refined memories over the document-sentence pair. First we use knowledge-enhanced self-attention (discussed in section 3.2.4) to fuse \(G\) into themselves, the outputs of which are represented as \(\tilde{H} \in \mathbb{R}^{d \times n}\). Then we process \(\tilde{H}\) with a BiLSTM, whose hidden state dimensionality is \(\frac{1}{2}d\). By concatenating the forward LSTM outputs
the backward LSTM outputs, we obtain the fine-grained memories \( H \in \mathbb{R}^{d \times n} \), which are the final document representations.

- Based on the fine-grained memories and the sentence context embeddings, the sense prediction layer generates the sense prediction. We first perform attention pooling on \( C_S \) to obtain a summary of the sentence:

\[
\epsilon = C_S \text{softmax}(\tanh(W_\epsilon C_S)\top v_\epsilon) \in \mathbb{R}^{2d}
\]  

(3)

where \( W_\epsilon \) and \( v_\epsilon \) are trainable parameters. Then, with \( \epsilon \) as a query, we compute a posterior distribution of all sense candidates in the list:

\[
\phi = \text{softmax}(\tanh(W_\phi \epsilon)\top v_\phi) \in \mathbb{R}^{n}
\]  

(4)

where \( W_\phi \) and \( v_\phi \) are trainable parameters. Thus, for the training, we minimize \(-\log(\phi, t)\) on each training sample whose labeled sense is \( t \). For the inference, we take the index of the maximum element as \( \phi \).

3.2.3. KNOWLEDGE-ENHANCED JOINT-ATTENTION

As a part of the coarse-grained memory layer, knowledge-enhanced joint-attention is aimed at fusing the sentence context embeddings \( C_S \) into the document context embeddings \( C_D \), where the key problem is to calculate the similarity between each document context embedding \( c_d \) (i.e., the \( i \)-th column in \( C_D \)) and each sentence context embedding \( c_s_j \) (i.e., the \( j \)-th column in \( C_S \)). To solve this problem, we incorporate a similarity function:

\[
f(c_d_i; c_s_j) = v_f [c_d_i; c_s_j; c_d_i \odot c_s_j] \in \mathbb{R}
\]  

(5)

where \( v_f \) is a trainable parameter; \( \odot \) represents element-wise multiplication. Since context embeddings contain high-level information, we believe that introducing the pre-extracted general knowledge into the calculation of such similarities will enhance the ability of the model to identify the boundaries of word senses and is helpful for the final disambiguation. Therefore, we use the pre-extracted general knowledge to construct the enhanced context embeddings. Specifically, for each word \( w \), whose context embedding is \( c_w \), to construct its enhanced context embedding \( c_w^+ \), first recall that we have extracted a set \( E_w \), which includes the positions of the document words that \( w \) is semantically connected to, thus by gathering the columns in \( C_D \) whose indexes are given by \( E_w \), we obtain the matching context embeddings \( Z \in \mathbb{R}^{d \times |E_w|} \). Then by constructing a \( c_w \)-attentive summary of \( Z \), we obtain the matching vector \( c_w^+ \) (if \( E_w = \emptyset \), which makes \( Z = \{ \} \), we will set \( c_w^+ = 0 \)):

\[
t_i = v_c\top\tanh(W_c z_i + U_c c_w) \in \mathbb{R}
\]  

(6)

\[
c_w^+ = Z \text{softmax}(\{t_1, \ldots, t_{|E_w|}\}) \in \mathbb{R}^d
\]  

(7)

where \( v_c, W_c, \) and \( U_c \) are trainable parameters; \( z_i \) represents the \( i \)-th column in \( Z \). Finally we pass the concatenation of \( c_w \) and \( c_w^+ \) through a dense layer with ReLU activation.
whose output dimensionality is $d$. Therefore we obtain the enhanced context embedding $\tilde{c}_w \in \mathbb{R}^d$.

Based on this context embeddings, to perform knowledge-enhanced joint-attention, first we construct a knowledge-enhanced similarity matrix $A \in \mathbb{R}^{n \times m}$, where each element $A_{i,j} = f(\tilde{c}_{d_i}, \tilde{c}_{s_j})$. Then we construct the document-attentive sentence summaries $R_S$ and the sentence-attentive document summaries $R_D$:

$$R_S = C_S \text{softmax}_r(A) \in \mathbb{R}^{d \times n}$$

$$R_D = C_D \text{softmax}_r(A) \text{softmax}_c(A) \in \mathbb{R}^{d \times n}$$

where $\text{softmax}_r$ represents softmax along the row dimension and $\text{softmax}_c$ along the column dimension. Finally we pass the concatenation of $C_D$, $R_S$, $C_D \odot R_S$, and $R_D \odot R_S$ through a dense layer with ReLU activation, whose output dimensionality is $d$. Thus, we obtain the outputs $G \in \mathbb{R}^{d \times n}$.

### 3.2.4. Knowledge-Enhanced Self-Attention

As a part of the fine-grained memory layer, knowledge-enhanced self-attention is aimed at fusing the coarse-grained memories $G$ into themselves. We use the pre-extracted general knowledge to guarantee that the fusion of coarse-grained memories for each document word will only involve a precise subset of the other document words. Specifically, for each document word $d_i$, whose coarse-grained memory is $g_{d_i}$ (i.e., the $i$-th column in $G$), to perform the fusion of coarse-grained memories, first recall that we have extracted a set $E_{d_i}$, which includes the positions of the other document words that $d_i$ is semantically connected to, thus by gathering the columns in $G$ whose indexes are given by $E_{d_i}$, we obtain the matching coarse-grained memories $Z \in \mathbb{R}^{d \times \vert E_{d_i} \vert}$. Then by constructing a $g_{d_i}^+$-attentive summary of $Z$, we obtain the matching vector $g_{d_i}^+$ (if $E_{d_i} = \emptyset$, which makes $Z = \emptyset$), we will set $g_{d_i}^+ = 0$):

$$t_i = v_g^+ \tanh(W_g z_i + U_g g_{d_i}) \in \mathbb{R}$$

$$g_{d_i}^+ = Z \text{softmax}\{t_1, ..., t_{\vert E_{d_i} \vert}\} \in \mathbb{R}^d$$

where $v_g$, $W_g$, and $U_g$ are trainable parameters. Finally we pass the concatenation of $g_{d_i}$ and $g_{d_i}^+$ through a dense layer with ReLU activation, whose output dimensionality is $d$. Therefore we obtain the fusion result $\tilde{h}_{d_i} \in \mathbb{R}^d$, and further the outputs $\tilde{H} = \{\tilde{h}_{d_1}, ..., \tilde{h}_{d_n}\} \in \mathbb{R}^{d \times n}$.

Our proposed neural model is quite different from the existing WSD models in that it uses semantic level inter-word connections, which are pre-extracted from the WSD dataset using the WordNet based data enrichment method, as explicit knowledge to assist the sense prediction of the target word. On one hand, the coarse-grained memory layer uses the explicit knowledge to assist both the document-to-sentence and sentence-to-document attentions. On the other hand, the fine-grained memory layer uses the explicit knowledge to assist the self-attention.

### 4. Experiments and Analysis

To evaluate the performance of our proposed semi-supervised neural system (PoKED), we conducted experiments on standard benchmark datasets proposed by (Raganato et al., 2017), i.e., Senseval-2 (S2), Senseval-3 (S3), SemEval-2007 (SE7), SemEval-2013 (SE13) and SemEval-2015 (SE15).

**Implementation.** To train the proposed unsupervised position-wise orthogonal (PoNet) pseudo-language model, we use BooksCorpus (Zhu et al., 2015) and English Wikipedia as part of our pretraining training data. In addition, we include Giga5 (Parker et al., 2011), ClueWeb 2012-B (extended from (Callan et al., 2009)), and CommonCrawl (Crawl) for pretraining. The 1M most frequent words in the corpus are chosen as the vocabulary. The dimension of word embedding is chosen to be 128. The position-wise codes leads to a dimension of 1024 for the input layer of the orthogonal framework. Then we append three hidden layers of dimension 2048. Additionally, we choose constant forgetting factors $\alpha = (0.5, 0.9)$ for the position-wise codes.

To implement our proposed supervised neural model, we exploit the Stanford CoreNLP (Manning et al., 2014) to pre-process datasets. With the outputs of the pipeline, we use the WordNet interface provided by NLTK (Bird & Loper, 2004) to perform the WordNet-based data enrichment method. Additionally, we implement knowledge-based attentive neural model using Tensorflow (Abadi et al., 2016) and train it on SemCor (Miller et al., 1994) corpus. For each BiLSTM, we set its hidden state size to 256. For the training, we use ADAM (Kingma & Ba, 2014) as our optimizer, set the learning rate to 0.001, and set the mini-batch size to 32. To avoid overfitting, we apply Dropout (Srivastava et al., 2014) with the value of 0.1, and apply early stopping with a patience of 3. To avoid the exploding gradient problem, we apply gradient clipping (Pascanu et al., 2013) with a cutoff threshold of 2. Besides, we also apply exponential moving average with a decay rate of 0.999.

Following (Raganato et al., 2017), (Luo et al., 2018) and (Hadiwinoto et al., 2019), we choose SE07, the smallest among these test sets, as the development set. When fine-tuning, we use the development set to find the optimal settings for our experiments. The reported WSD task results in F1-score are averaged over three runs.

**Experimental results.** We performed a comparison with three configurations of our model, namely: PoKED$_\alpha$, obtained using our pre-trained position-wise orthogonal (PoNet) context embeddings with general knowledge; PoKED$_\beta$, obtained using Roberta (Liu et al., 2019) and general knowledge; PoKED$_\gamma$, obtained using XLNet (Yang et al., 2019) and general knowledge.
As comparison systems we included four semi-supervised approaches mentioned above, namely: Babelfy (Moro et al., 2014), \textit{pprw2w}, the best configuration of UKB (Agirre et al., 2018), WSD-TM (Chaplot & Salakhutdinov, 2018), and WSDG (Tripodi &Navigli, 2019). In addition, we also report the performances of relevant supervised models, namely: IMS (Zhong & Ng, 2010), IMS\textsubscript{w2v} (Iacobacci et al., 2016), Yuan\textsubscript{STM} (Yuan et al., 2016), Raganato\textsubscript{BLSTM} (Raganato et al., 2017), GAS (Luo et al., 2018), fastSense (Uslu et al., 2018), GLU-LW (Hadiwinoto et al., 2019) and Gloss-BERT (Huang et al., 2019).

The results of our evaluation are shown in Table 1. As we can see our models achieve state-of-the-art performances on four datasets, (i.e., S2, S3, SE07, SE15). It is worth noting that, on SE13 and SE15 datasets, ours perform better than most supervised systems. In general, the gap between supervised and semi-supervised systems is narrowed. This encourages new research in this direction. Our models perform particularly well on the disambiguation of \textit{nouns} and \textit{adjectives}.

**Effect of general knowledge extraction.** We obtain seven enriched WSD datasets by setting \(\tau\) from zero to six separately, and train a different PoKD\(_\alpha\) system on each enriched WSD dataset. As shown in Table 2, by increasing \(\tau\) from zero to six in the data enrichment method, the amount of general knowledge rises monotonically, but the F1-score of our proposed PoKD\(_\alpha\) first rises until \(\tau\) reaches three for SE07 and SE15 datasets, and reaches four for S2, S3 and SE13 datasets, respectively, and then drops. We can conclude that the explicit knowledge provided by the WordNet-based data enrichment method plays an effective role in the training of our proposed PoKD\(_\alpha\) system.

**Ablation study on knowledge-enhancement.** We have conducted an ablation study and obtained a version without knowledge-enhancement based on PoKD\(_\alpha\). Specifically, we replace knowledge-enhanced joint-attention and knowledge-enhanced self-attention with full bipartite attention and standard dot-scale attention, respectively. We observe that the performance of the model without knowledge-enhancement drops dramatically compared with that of PoKD\(_\alpha\), especially with the SE15 dataset. In this case, F1-score declined by 5.4%, 70.5 vs. 65.1. It indicates that human semantic knowledge is helping with the WSD task remarkably, and plays an important role in our semi-supervised neural WSD system.

**Quantitative analysis of the hunger for data.** Specifically, instead of using all the training examples, we produce several training subsets (i.e., subsets of the training examples) so as to study the relationship between the proportion of the available training sentences and the performance. We produce each training subset by sampling a specific number of sentences from all the sentences relevant to each document. By separately sampling 1, 2, 3, and 4 sentences on each document, we obtain four training subsets, which separately contain 20\%, 40\%, 60\%, and 80\% of the training samples. As shown in Figure 5, with PoKD\(_\alpha\) trained on these training subsets, we evaluate its performance on the SE15, S3 and ALL, and find that PoKD\(_\alpha\) performs much better than MFS baseline even when only 80\% of the training samples are used. That is, when only a subset of the training examples is available, PoKD\(_\alpha\) is still comparable to the state-of-the-art WSD models.

**Discussion.** According to the experimental results, PoKD not merely achieves state-of-the-art performances on most datasets, but performs better than most supervised systems. The reasons for these achievements, we believe, are as follows.

First, some inter-word semantic connections are distracting for the disambiguation of word sense. For example, the inter-word semantic connection between “ballpoint” and “pen” makes no sense given the context “Little John was looking for his toy box. Finally, he found it. The box was in the pen.” It is the knowledge-enhanced attention mechanisms that enable PoKD to ignore such distracting inter-word semantic connections so that only the important ones are used.

Second, PoKD is designed to utilize the pre-extracted inter-word semantic connections extracted by the data enrichment method. Several approaches have been presented in recent years to make use of ontologies or types (such as (Dasigi et al., 2017)) to represent word tokens based on knowledge bases (e.g., WordNet). However, they neglect the importance of inter-word semantic connections from document-sentence pairs. Therefore, in this paper, we explore an explicit (i.e., understandable and controllable) way
to utilize general knowledge. Some inter-word semantic connections, especially those obtained through multi-hop semantic relation chains, enhance the ability of the model to identify the boundaries of word senses and is helpful for the final disambiguation.

Finally, an inter-word semantic connection extracted from a document-sentence pair usually also appears in many other document-sentence pairs; therefore it is very likely that the inter-word semantic connections extracted from a small number of training examples cover a larger amount of training examples. That is, we are using more training examples for model optimization than the available ones.

5. Conclusion

In this paper, we propose a semi-supervised neural system (PoKED), which incorporates human semantic knowledge into the neural network architectures for the WSD task. Specifically, inter-word semantic connections are first extracted from each given document by a WordNet-based data enrichment method, and then provided as general knowledge to an end-to-end WSD model, which explicitly uses the general knowledge to assist its attention mechanisms. Experimental results show that PoKED achieves better performance than the previous state-of-the-art knowledge-based models.

Table 1. Comparison with state-of-the-art algorithms: semi-supervised or knowledge-based (semi-sup.), and supervised (sup.). MFS refers to the Most Frequent Sense heuristic computed on SemCor (Miller et al., 1994) on each dataset. The results are provided as F1-score. Bold font indicates best systems. Results in the first and last blocks come from (Tripodi & Navigli, 2019; Hadiwinoto et al., 2019; Huang et al., 2019).
